Chronic and late effects: how physical activity can help

An exercise programme can improve patients’ physical ability to function, lift their mood and may even lower their chance of recurrence. The coordinator of the ground-breaking Glasgow study presents the evidence in favour of including individualised exercise interventions as an integral part of patient care.

One million people will be living with a diagnosis of cancer in the UK alone by 2030 (www.macmillan.org.uk). This is equivalent to more than 7 out of every 100 members of the adult population – a proportion that will be reflected across much of Europe, where incidence and survival rates are broadly similar. The challenge in ensuring that these survivors enjoy a good quality of life is to address the chronic or late-appearing side-effects of cancer and cancer treatments. These include fatigue, which is one of the most debilitating long-term effects of cancer; weight changes (either weight gain or loss); loss of bone density, including osteoporosis; cardiotoxicity; lymphoedema; psychological problems including anxiety, depression, fear of recurrence and cognitive dysfunction; and limited range of movement.

A US study showed that more than half of cancer survivors (53%) had problems functioning, with at least one functional limitation, compared

European School of Oncology e-grandround

The European School of Oncology presents weekly e-grandrounds which offer participants the chance to discuss a range of cutting-edge issues with leading European experts. One of these is selected for publication in each issue of Cancer World.

In this issue Anna Campbell, University of Dundee, Scotland, reviews the latest evidence on the role of exercise in cancer rehabilitation. Dominik Berthold, University Hospital of Canton Vaud, Lausanne, Switzerland, poses questions arising during the e-grandround live presentation, which was held in collaboration with the European Oncology Nursing Society (EONS).

Summarised by Susan Mayor.

The recorded version of this and other e-grandrounds is available at www.e-eso.net
to only 21% of people of the same age who had not had cancer (Ann Epidemiol 2006, 16:197–205). The study was undertaken with an elderly population, and the common functional problems were: crouching/kneeling; standing for two hours; walking quarter of a mile (0.4 km); lifting or carrying a load of 10 lb (4.5 kg); and standing up out of a chair. These movements are all the basis of daily activities needed for housework, shopping and similar tasks, suggesting that functional aspects of quality of life tend to be quite dramatically reduced after a cancer diagnosis.

**Exercise-based cancer rehabilitation: the evidence**

The number of high-quality studies in this field is increasing exponentially each year. They show that physical activity can reduce the functional loss (cardiovascular and muscular) that occurs with cancer and its treatment, and can reduce some of the chronic or late-appearing side-effects of treatment, including fatigue, depression and weight gain. Exercise-based rehabilitation can also reduce some of the long-term reliance on health services. Emerging epidemiological evidence suggests that being physically active reduces the risk of the cancer recurring, as well as all-cause mortality, for breast, prostate and colorectal cancers. As rehabilitation programmes are already available for coronary heart disease, diabetes, preventing falls and the lung disease COPD, programmes for cancer survivors can tag into or copy programmes that have been tried and tested for other chronic conditions.

**During treatment**

A systematic review of high-quality, randomised controlled studies of physical activity as an intervention during adjuvant treatment for cancer – during chemotherapy, radiotherapy or after surgery – shows that physical function, in terms of cardiovascular function and muscular strength, improves significantly (grade A evidence; J Cancer Surviv 2010, 4:87–100).

The 17 randomised controlled trials all showed a small to moderate effect in improving cardiovascular fitness or muscular strength in patients taking part in a physical activity programme during adjuvant treatment.

Some studies have shown physical activity can reduce fatigue during treatment, but the overall effect is not very large. However, the good
news is that being physically active during treatment does not increase tiredness. Anxiety, self-esteem, quality of life and depression show small improvements with physical activity during treatment. Also exercise interventions aid in significantly reducing body fat and increasing lean muscle mass. The overall take home message is that it is safe and effective to give an appropriate programme of physical activity while on adjuvant treatment. This can help prevent the functional decline that can occur during and after cancer treatment.

**Question.** There is a modest increase in physical function with physical activity. Do you have any information on age subgroups? Will a patient who is 80 years old benefit as much as a younger person with non-Hodgkin lymphoma at the age of 20?

**Answer.** The majority of studies mentioned in this report are with women with breast cancer with an average age of 50–60. I believe that a similar effect will be found irrespective of age, but perhaps a younger person with non-Hodgkin lymphoma would gain more fitness from a physical activity intervention, while a frail elderly person might gain more active daily living and confidence. The results will vary with the cancer type and the patient’s age and condition.

**After treatment**

What about giving an exercise intervention in a patient who has finished adjuvant treatment? Results here are more significant. Exercise interventions achieve large increases in muscle strength (effect size [ES] 0.90 in seven randomised controlled trials) as well as significant improvement in cardiovascular fitness (ES 0.32 in 14 RCTs). For many but not all patients, this time point, just after treatment, is when they are ready to start an exercise programme. Fatigue levels also show a significant reduction with exercise interventions. Well-being improves more significantly with activity after treatment, and there are small reductions in body fat and increases in muscle mass. It is important to note that these trials involved only an exercise intervention; studies incorporating both exercise and diet may give even better results for positive changes in body composition.

Finally, some new studies have looked at the effect of exercise on bone density. Reduced bone turnover can occur with hormonal therapies, potentially reducing bone density. Resistance exercise programmes can help reduce the risk of bone thinning, but the results of different trials to date are inconsistent.

Other benefits of exercise are being explored in relation to some of the late effects of cancer treatment. As well as improving bone health, studies have shown exercise programmes can improve range of movement. Activity programmes designed for individuals may prevent lymphoedema, and studies have shown that exercise does not exacerbate lymphoedema in patients who already have the condition. Further studies have shown improved mood, better regulation of insulin, reduced cardiotoxicity and improved immune system function with exercise.

A smaller number of studies have looked at the effects of exercise in people with advanced or terminal cancer. A systematic review of six small studies investigating physical activity during palliative care showed some benefit. One study showed that home-based, seated exercises prevented decline in quality of life (Oncol Nurs Forum 2004, 31:977–983). Supervised group exercise for six weeks improved fitness, functional ability, emotional well-being, fatigue, dyspnoea and anorexia (J Pain Symptom Manage 2006, 31:421–430). The key message in a palliative setting is that the patient’s preference is important. The aim is not necessarily to improve fitness, but to maintain independence and wellbeing towards the end of life.

**Impact of physical activity on cancer recurrence: the evidence**

Kenfield and colleagues followed 2705 men diagnosed with prostate cancer over 10 years, monitoring activity levels. Results showed that the number of deaths in total was 36% lower in men who walked an average of one hour each day (7+ hours per week). It was 49% lower among men taking three or more hours of vigorous activity each week, with 61% fewer cancer deaths (JCO 2011; 29:727–732).

The strongest beneficial effects of physical activity on disease recurrence and risk of death has been observed in longitudinal studies of breast cancer survivors. A systematic review of nine high-quality, prospective cohort studies following breast cancer survivors over time showed that undertaking leisure-time physical activity involving moderate-intensity exercise for 30 minutes most days each week was associated with a 30% reduction in breast cancer mortality risk when compared to a sedentary lifestyle with virtually no physical activity (Maturitas 2010, 66:5–15; Med Oncol 2011, 28:753–765). Two longitudinal studies have shown that colorectal cancer recurrence risk and mortality is reduced by about 50% with six hours of moderate-intensity physical activity each week (JCO 2006, 24:3535–41).
Physical activity programmes can help:
- Improve functional status before treatment or prevent/delay functional decline during treatment:
  - Maintain/optimise cardio-respiratory function
  - Maintain muscle mass (lean body mass) and strength
  - Maintain joint range of motion/muscle/connective tissue length.
- Address treatment-specific impairments during and after treatment, including: pain, fatigue, muscular weakness (specific), deficits in joint range of motion, poor balance or co-ordination, lymphoedema, peripheral neuropathy, bone thinning and steroid-induced cardiomyopathy.
- Optimise general health in the recovery period after cancer treatment.

What do guidelines recommend?
During cancer treatment (surgery, chemotherapy and radiotherapy), guidelines recommend that patients should exercise to tolerance (Med Sci Sports Exerc 2010; 42:1409–26). This means that interventions should be individualised for each patient according to how fit they were before developing cancer, their current treatment, and the side-effects they encounter. After treatment, and when patients are feeling stronger, they should try to accumulate about 20–30 minutes of moderate-intensity cardiovascular fitness training three to five days per week, and also incorporate muscular strength and endurance training twice a week. Activity to maintain balance and flexibility is also beneficial. Physical activity programmes should be individualised, based on a patient’s needs, goals and exercise preferences, and taking account of any barriers to exercise, including long-term side-effects related to their treatment and disease. Brisk walking is a great simple and easy cardiovascular activity that patients can do to get health benefits – even five to ten minutes’ walk round the block or to the shops can be enough to make a difference.

Question. Research shows a risk reduction of 30% or 40% with exercise for the three most common cancers, and this exercise does not need to be intensive but can just be walking for 20–30 minutes a day. To me that just looks amazing. It’s extremely cost-effective compared to the costs of cancer treatments. Why isn’t there a major programme in the UK or elsewhere to help cancer patients take exercise?

Answer. There are now a number of programmes that are beginning to emerge throughout Europe. Here at Dundee we have a programme called MoveMore, available for any person living with cancer – it offers home-based programmes with a DVD and booklet, one-to-one consultations, gym instruction and group- and water-based exercise programmes. A sample of approximately 12 different types of programme (e.g. hospital-based, home-based, individual, group, etc) is being evaluated by Macmillan, a UK cancer charity, for improvements in quality of life, active daily living and cost–benefit.
Question to the live webcast participants. Patients at my centre have no formal access to exercise rehabilitation. Do yours?

Responses. Yes: 44%. No: 56%.

Question to participants. In your opinions, how many patients could benefit from such an intervention?

Responses. Most participants considered 30–50% of cancer patients would benefit.

For a lot of people who have not participated in any structured physical activity for a long time, a cancer diagnosis can be 'a teachable moment' (JCO 2005, 23:5814–30). Being diagnosed with cancer can increase a person’s motivation to make lifestyle changes, including incorporating exercise into their lives. However, figures for the US – which are very likely to be true also for other countries – show the number of people doing the recommended level of 30 minutes moderate-intensity activity on most days of the week is very low (Eur J Cancer Care 2006, 14:34–43).

Only 30–40% of the population take the recommended amount of exercise before being diagnosed with cancer, and this falls to only about 5% of patients on treatment and 20% off treatment.

**Putting the evidence into practice**

In 2000, I carried out a small pilot study which showed that ‘rest is not best’ during breast cancer treatment, but that physical activity could improve quality of life. In 2003, my colleagues and I began a larger study funded by Cancer Research UK – the Glasgow Study – that randomised 203 women on chemotherapy or radiotherapy for breast cancer to attend group exercise classes (a combination of cardiovascular and strength training) twice a week for 12 weeks, or to the usual care group of no structured exercise. After 12 weeks, women taking part in the exercise programme (held in community-based settings) had improved significantly in walking pace, weekly activities, shoulder mobility, breast cancer specific quality of life, and positive mood. Six months later, women who had been randomised to the exercise intervention during treatment still had better overall quality of life in terms of physical functioning, positive mood, and

Only a minority of people meet daily recommended levels of physical activity even when they are healthy

It took 18 months for women in the control group to catch up with those on the exercise programme in terms of sustained walking speed. Five years on, women on the programme were still doing 2.5 hours more physical activity a week on average and reported more positive mood.

In light of the results of that study, the city of Glasgow has now introduced the Active ABC – Active After Breast Cancer – programme for any woman diagnosed with breast cancer in the past five years. It provides 24 free sessions led by trained fitness professionals followed by sessions on health behaviour change. The programme works by self-referral, but patients can be signposted by health professionals. A national vocational qualification has been developed to train people to become cancer rehabilitation specialists (www.canrehab.co.uk) and there are now more than 200 qualified cancer exercise specialists in the UK. Dundee University is setting up a cancer rehabilitation centre for training, research and practice. The aim, as mentioned earlier, is to make exercise-based rehabilitation a sustainable part of every cancer survivors’ care pathway.

**Summing up**

Keeping physically active after a cancer diagnosis appears to be a safe and effective way of improving physical, functional, social and emotional aspects of quality of life. Programmes should be individualised. The key message for patients is that a little physical activity is better than nothing, and they should avoid being sedentary. Right from their diagnosis, patients should have information that being active can be helpful and health professionals need to be aware of the strong evidence for the benefits of exercise. For the future, more research is needed on cancer-specific guidelines for physical activity, into mechanisms and into ways to improve behaviour change.
